

The same woman advises a larger family when the births are daughters

Advised completed family size in each round of the lifecycle game

One observation per woman per round; each woman plays all three rounds, so the contrast holds the woman fixed and varies only the sex of the births she faces. The paired within-woman difference is 0.72 children (se 0.05, $t=13.8$, $n=855$ women), a 31 percent increase over the all-son round; 47 percent of women advise more children in the all-daughter round and 7 percent fewer. The random round sits with the all-son round because a son arrives within the first two births for 76 percent of women there. Bars are 95 percent confidence intervals.
